Ribbed moraines formed during the retreat of the Scandinavian ice sheet from eastern Himmerland, NE Jylland, Denmark

Hans Lerche, Peter Roll Jakobsen and Stig A. Schack Pedersen

The glacial geology of Himmerland in the north-eastern part of Jylland, south of Limfjorden (Fig. 1) has never received any special attention. However, the occurrence of parallel ridges south of Torup was mentioned by Milthers (1948) who interpreted them as marginal moraines. The ridges were recently studied during mapping of eastern Himmerland. Systematic geological mapping of the area north and south of Mariager Fjord started in 2009 and was completed in 2013 (map sheet 1316 III; Pedersen et al. 2013). This was followed by the map sheet to the north (1316 IV). During the recent mapping the extent of the terrain with parallel ridges was determined (Fig. 2); the western boundary is found in Rold Skov (Pedersen & Jakobsen 2005) and the eastern boundary follows an ancient coastline in eastern Himmerland. The most impressive parallel ridges occur in a forested area east of Madum Sø where the top level of the ridge crests reaches an elevation of 95 m a.s.l. However, the majority of the crests are at 60–70 m a.s.l. and most of the ridges are c. 10–15 m high. The sediments in the ridges are dominated by coarse-grained sand and gravel, and accumulations of erratic boulders are found on the surface of the ridges.

After completion of the mapping of the area, we decided to make a detailed investigation of the ridges using ground-penetrating radar (GPR) to map the internal structures of the ridges. We also studied sections in a small gravel pit at the northern boundary of Siem Skov (Figs 3, 4).

The aim of this paper is to describe the terrain with parallel ridges, which we interpret as ribbed moraines. We discuss the geological setting of the ridges in relation to the data acquired during the systematic geological mapping and the accompanying GPR survey. A glaciodynamic model for the formation of the ridges is proposed related to the recession of the ice that had its source area in south central Sweden.
Geological setting

The bedrock in Himmerland is dominated by Maastrichtian chalk which is exposed in pits throughout the region. An erosional unconformity separates chalk from Quaternary deposits. Major parts of the region between Mariager Fjord and Limfjorden are covered by glaciofluvial sand that reaches a thickness of c. 40 m at Hadsund. In the small gravel pit at the northern boundary of Siem Skov, the succession begins with a glaciolacustrine unit, which increases in thickness to the east. This unit is interpreted as a palaeo-Kattegat deposit and may correlate with the Lønstrup Klint Formation in Vendsyssel (Pedersen 2005). It is overlain by glacioluvial sand and gravel that may correlate with the Rubjerg Knude Formation (Pedersen 2005). These proglacial deposits of the glacidynamic sequence (according to the concept of Pedersen 2012) are overlain by c. 3 m of till. The till is classified as a sandy till; it contains indicator boulders from the Oslo Fjord region and its fabric indicates an ice-flow direction from north to south. Based on this ice movement direction, the till is correlated with the Kattegat Till Formation (Houmark-Nielsen & Kjær 2003; Pedersen 2005). The top of the till is at 56 m a.s.l. in Siem Skov where it forms the base of the 10–25 m high ridges.

Meltwater related to the Swedish Ice Advance only played a small role in the region with the parallel ridges. To the west, glaciofluvial deposits from the Swedish Ice Advance are found in the upper part of the Rebild Bakker (Pedersen & Jakobsen 2005). After the parallel ridges had formed, depressions were created in the landscape due to melting of bodies of stagnant ice that were left from the retreating ice front. During the early Holocene valleys were eroded when the relative sea level was low.

Geomorphology of the parallel ridges

The elongate ridges cover an area of 15 × 8 km. Most of them are N–S-oriented, but there are NW–SE-oriented ridges in the north-western part of the area. The ridge density is highest in the central part of the area, in Hellum Skov and Siem Skov (Pedersen 2005). It is overlain by glaciofluvial sand and gravel that may correlate with the Rubjerg Knude Formation. These proglacial deposits of the glacidynamic sequence (according to the concept of Pedersen 2012) are overlain by c. 3 m of till. The till is classified as a sandy till; it contains indicator boulders from the Oslo Fjord region and its fabric indicates an ice-flow direction from north to south. Based on this ice movement direction, the till is correlated with the Kattegat Till Formation (Houmark-Nielsen & Kjær 2003; Pedersen 2005). The top of the till is at 56 m a.s.l. in Siem Skov where it forms the base of the 10–25 m high ridges.

Meltwater related to the Swedish Ice Advance only played a small role in the region with the parallel ridges. To the west, glaciofluvial deposits from the Swedish Ice Advance are found in the upper part of the Rebild Bakker (Pedersen & Jakobsen 2005). After the parallel ridges had formed, depressions were created in the landscape due to melting of bodies of stagnant ice that were left from the retreating ice front. During the early Holocene valleys were eroded when the relative sea level was low.

Georadar survey of the parallel ridges

In September 2013, ground penetrating radar (GPR) surveys were carried out in Hellum Skov where the most pronounced ridge terrain is found. An EKKO 100TM device mounted on a cart was used, and six lines perpendicular to the ridges were recorded; five lines in the northern part of the forest and one line c. 1 km to the south. Transmitter voltage was 400 V and antenna frequency was centered at 100 MHz. The antennas were oriented broadside to the survey direction and separated by 1 m. Traces were recorded every 20 cm and consist of stacks of eight.

Two representative profiles, LINE0007 and LINE0014, illustrate the internal architecture of the ridges (Fig. 5). Assuming a mean velocity of 0.1 m/ns, 1 m equals 20 ns. In LINE0014 the layers below the ridges are predominantly...
subparallel anticlines, whereas layers below depressions are dominantly subparallel synclines. In both profiles two types of faults are found: (1) small, dominantly eastward-dipping faults and (2) larger, possibly superimposed folded thrust faults, which can be traced from near the surface down to 7–10 m below the surface (Fig. 5).

**Formation of the ridges**

The small E-dipping faults recognised in the GPR profiles are interpreted as thrust faults caused by pushing from the east. Small W-dipping faults may indicate landslides on steep ridge flanks. Large thrust faults are interpreted as listric faults with décollement surfaces c. 7–10 m below the ground. The folded lower layers of LINE0014 suggest ductile deformation within the ridges and the depressions.

GPR data indicate that the ridges were formed by ice pushing from the east under non-permafrost conditions. We suggest that the ridges reflect a net ice recession with a mean rate of c. 50 m/year, but with a number of small advances (Fig. 6). The east–west extent with ridges is almost 10 km wide, corresponding to a period of c. 200 years. A similar magnitude of recession rate of the Scandinavian Ice Sheet has been suggested for Vendsyssel, where recession from the coastal area along Kattegat north of Limfjorden is estimated to have occurred in the interval from 19 to 18.5 ka (Sandersen et al. 2009). We suggest that shortly after termination of the Last Glacial Maximum temperature increased rapidly, which lead to a significant recession of the ice margin.

The moraines show some similarities to de Geer moraines (De Geer 1940; Lundquist 1986; Lundquist & Viborg 1998; Lindén & Möller 2005). However, de Geer moraines formed in water depths of 150–250 m, during retreat of a grounding line with a calving glacier front. In contrast, the Himmerland moraines formed on dry land.
Conclusions

As part of the systematic mapping of eastern Himmerland, a detailed investigation was made of a terrain with parallel ridges located in a 120 km$^2$ large area centred on Siem Skov. The individual ridges are up to c. 2.5 km long. The ridges are 10–25 m high, and the spacing between the ridge crests varies from 50 to 100 m. The parallel ridges are interpreted as ribbed moraines that formed during recession of the ice margin at c. 19 ka. The detailed architecture of the ridges was investigated by GPR surveys which show an integrated depositional and deformational dynamic picture with narrow and steep-sided depressions filled with flow-till materials contemporaneous with fold-push and up-thrusting.
